

Model selection: three search strategies

Pick a good subset of the predictors $X_1, \dots, X_p$.

Setup

A model uses a subset $S \subseteq \{X_1, \dots, X_p\}$. Score each model with a criterion C .

Use AIC, BIC, or cross-validation error (a lower C is better). All three methods share this score.

Best subset

Check every subset.

Forward selection

Grow from nothing.

Backward selection

Prune from everything.

	every subset	$S = \{ \}$ (empty)	$S = \{X_1, \dots, X_p\}$
Start			
The move	Fit all subsets. Keep the best at each size k .	Add the predictor that improves C the most. Repeat.	Drop the predictor that hurts C the least. Repeat.
Search path	$k=0$  $k=1$     $k=2$      $k=3$     $k=4$   compare best per size	$X_1 \ X_2 \ X_3 \ X_4$  start   + X_3   + X_1   + X_4   + X_2	$X_1 \ X_2 \ X_3 \ X_4$  start   - X_3   - X_1   - X_4   - X_2
	fits 2^p models in total		
Models fit	2^p	$1 + \frac{p(p+1)}{2}$	$1 + \frac{p(p+1)}{2}$ (needs $n > p$)

Then choose

Pick the model with the best C among the candidates each method produced.

Why the strategies differ

Best subset checks every model, so it finds the best subset for each size. But 2^p grows fast.

Forward and backward are greedy. They are cheap, but they follow one path, so they can miss the best subset.

Backward needs more observations than predictors ($n > p$) to fit the full model at the start.

 predictor in the model  predictor left out  changed this step  best model of that size
